- *Conformal Field Theory* (“Yellow Book”) by Francesco, Mathieu, Senechal.

Why study conformal field theory (CFT)?

- CFT provides a good description of systems at or near criticality.
- CFTs are the only true quantum field theories (QFTs), since they are cutoff-independent. One can think of QFTs as perturbations of CFTs. CFTs correspond to renormalization groups of fixed points, which dominate an effective theory at or near criticality.
- CFTs can be made, by and large, mathematically rigorous, at least in $(1+1)$ -dimensional theories. There are three major competing mathematical descriptions for CFT, and advances are being made towards a single, unifying description.

Prerequisites for this material:

- Advanced quantum mechanics
E.g, many-body theory and Fock spaces.
- Classical field theory
E.g., symplectic geometry.
- Quantum field theory.
- Advanced quantum field theory.

What is CFT?

- A *conformal field theory* is a field theory, quantum or classical, that is invariant, or symmetric, under a group of transformations called the *conformal group* G .
- In a classical field theory, this means that the equations of motion are left invariant.
- In a quantum field theory, this means that, by Wigner’s theorem, there is a projective unitary representation of the group G . In other words, symmetries, or transformations, that leave the transition amplitude invariant, are realized, up to a phase, by (anti)unitary operators.

Conformal Transformations in d Dimensions

Let $M = \mathbb{R}^{p,q}$ be a manifold \mathbb{R}^d , where $d = p + q$, and $p, q \in \mathbb{Z}_{\geq 0}$. To this manifold, assign the metric

$$g_{\mu\nu} \equiv \eta_{\mu\nu} = \text{diag}(1, 1, \dots, 1, -1, -1, \dots, -1) \quad (1)$$

With the first p entries equal to one, and the last q entries equal to minus one. Note that this is not necessarily a Riemannian metric, since the signature can be negative. We have a few cases of interest for this metric

- $p = d$, Riemannian.
- $p = d - 1$, $q = 1$, Lorentz.
- $q > 1$, e.g., $q = 2$, AdS-CFT correspondence.

A conformal transformation leaves the metric invariant up to a scale factor.

Consider a smooth change of coordinates

$$x \rightarrow x' = x'(x) \text{ , with } x = (x^1, x^2, \dots, x^p, x^{p+1}, \dots, x^{p+q}) \quad (2)$$

Such that the metric, a type-(2, 0) tensor, undergoes an *active coordinate* transformation as

$$g_{\mu\nu}(x) \rightarrow g'_{\mu\nu}(x') \equiv \frac{\partial x^\alpha}{\partial x'^\mu} \frac{\partial x^\beta}{\partial x'^\nu} g_{\alpha\beta}(x) \quad (3)$$

And then impose the condition

$$g'_{\mu\nu}(x') = \Omega(x') g_{\mu\nu}(x'). \quad (4)$$

Where $\Omega(x) > 0$ is the (local) scale factor. Note that if the scale factor is zero, then we have a singularity, which we will discuss later. A transformation that obeys the last line is called *conformal*, and these transformations preserve angles

$$\angle\theta = \frac{g_{\mu\nu} u^\mu v^\nu}{\sqrt{(g_{\mu\nu} u^\mu v^\nu)^2}}. \quad (5)$$

The *conformal group* of a manifold M is denoted by $\text{Conf}(M)$, and is the connected component of the group of all conformal transformations of M containing the identity, in a compact, open topology.

So, in a quantum conformal field theory, we are looking for a Hilbert space \mathcal{H} and a projective unitary representation of the group G for *local* QFTs

$$G \rightarrow \pi(G). \quad (6)$$

This is unexpectedly nontrivial, and makes for a very rich field of study, since there is a tension between knowing the unitary representations of symmetries

and demanding that the representation is locally implementable.

To classify the conformal group on our chosen manifold $G = \text{Conf}(\mathbb{R}^{p,q})$, consider an infinitesimal conformal (active coordinate) transformation on the spacetime coordinates

$$x^\mu \rightarrow x'^\mu = x^\mu + \epsilon^\mu(x) \quad (7)$$

Which must leave the metric invariant up to the scale factor $\Omega(x)$. This places constraints on ϵ (**Exercise**)

$$g_{\mu\nu} \rightarrow g'_{\mu\nu} = g_{\mu\nu} + (\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu) + \mathcal{O}(\epsilon^2). \quad (8)$$

To satisfy the constraint placed by conformal invariance on the metric (c.f., $g_{\mu\nu} \rightarrow g'_{\mu\nu}(x') = \Omega(x')g_{\mu\nu}(x')$), as well as the constraint that the conformally transformed metric is still proportional to the diagonal flat spacetime metric $g'_{\mu\nu} \propto \eta_{\mu\nu}$, we must have that the second term is also diagonal, proportional to $\eta_{\mu\nu}$

$$(\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu) \propto \eta_{\mu\nu} \quad (9)$$

$$\implies (\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu) = \text{constant} \cdot \eta_{\mu\nu} \quad (10)$$

Take the trace of each side, set $\mu = \nu$, and solve for the constant

$$\text{constant} = \frac{2(\partial \cdot \epsilon)}{d} \quad (11)$$

So, the conformal transformation on the metric reads, tossing out higher order terms,

$$g'_{\mu\nu} = g_{\mu\nu} + \frac{2(\partial \cdot \epsilon)}{d} g_{\mu\nu}. \quad (12)$$

And substituting into the proportionality relation from above, we have

$$(\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu) = \frac{2}{d} (\partial \cdot \epsilon) \eta_{\mu\nu}. \quad (13)$$

Combining this with the conformal transformation of the metric and comparing to the metric transformation law, we get that the scale factor $\Omega(x)$ for the conformal transformation of the spacetime metric is

$$\Omega(x) = 1 + \frac{2}{d} (\partial \cdot \epsilon). \quad (14)$$

Then it follows from $(\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu) = \frac{2}{d} (\partial \cdot \epsilon) \eta_{\mu\nu}$, expanding and equating mixed partial derivatives to third order, and we get d^2 partial differential equations of the form (**Exercise**)

$$(\eta_{\mu\nu} \square + (d-2) \partial_\mu \partial_\nu) (\partial \cdot \epsilon) = 0 \quad (15)$$

Where $\square = \eta^{\mu\nu} \partial_\mu \partial_\nu$ is the d'Alembertian operator.

Classification of Infinitesimal Conformal Translations for $d > 2$

By examining the condition for ϵ and the d^2 equations

$$(\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu) = \frac{2}{d}(\partial \cdot \epsilon)\eta_{\mu\nu} \quad (16)$$

$$(\eta_{\mu\nu}\square + (d-2)\partial_\mu\partial_\nu)(\partial \cdot \epsilon) = 0 \quad (17)$$

We find that third order derivatives of $\epsilon(x)$ vanish and $\epsilon(x)$ is at most quadratic.

This leaves four types of infinitesimal transformations, defined via ϵ , allowable in a conformal transformation: one constant, two linear, and one quadratic in spacetime coordinates.

1. Spacetime translations

$$\epsilon = a^\mu.$$

2. Rotations

$$\epsilon^\mu = \omega^\mu{}_\nu x^\nu, \omega \text{ antisymmetric.}$$

3. Scale transformations

$$\epsilon^\mu = \lambda x^\mu, \lambda > 0.$$

4. Special conformal transformations (SCT; inversion through a sphere)

$$\epsilon^\mu = b^\mu x^2 - 2x^\mu(b \cdot x).$$

Note that Lorentz and Poincaré transformations are always subgroups of the conformal group, leaving the metric invariant. since ω corresponds to boosts and Euclidean affine rotations complete the Poincaré group.

Theorem

Every conformal transformation that acts on an connected subset of Minkowski space, including the whole space itself, $\varphi : U \subset \mathbb{R}^{p,q}$, where $p + q > 2$, is a composition of

- a translation

$$x^\mu \rightarrow x^\mu + a^\mu, \text{ where } a \in \mathbb{R}^d,$$

- an orthogonal transformation (rotation)

$$x \rightarrow \Lambda x, \text{ where } \Lambda \in O(p, q),$$

- a dilation (scale)

$$x^\mu \rightarrow \lambda x^\mu, \text{ where } \lambda \in \mathbb{R}^+,$$

- and an SCT

$$x \rightarrow \frac{x^\mu - b x^2}{1 - 2b \cdot x + b^2 x^2}, \text{ where } b \in \mathbb{R}^q.$$

Note that it is possible to find a vector b such that the denominator is equal to zero, the SCT is not invertible, and this is no longer a group. Also note that if we don't compactify the space and include ∞ as a point available to the conformal transformation, the group becomes significantly smaller and more constrained.

Classification of Infinitesimal Conformal Translations for $d = 2$

If $d = 2$, the spacetime metric becomes the identity

$$g_{\mu\nu} = \delta_{\mu\nu} \quad (18)$$

And $(\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu) = \frac{2}{d}(\partial \cdot \epsilon)\eta_{\mu\nu}$ becomes the Cauchy-Riemann equations and $\epsilon(x)$ is complex-valued, complex-differentiable, and analytic

$$\partial_1 \epsilon_1 = \partial_2 \epsilon_2 \text{ and } \partial_1 \epsilon_2 = -\partial_2 \epsilon_1. \quad (19)$$

Introduce the complex coordinates

$$z = x^1 + ix^2 \text{ and } \bar{z} = x^1 - ix^2. \quad (20)$$

Then we can complexify ϵ as

$$\epsilon(z) = \epsilon^1 + i\epsilon^2 \text{ and } \bar{\epsilon}(\bar{z}) = \epsilon^1 - i\epsilon^2. \quad (21)$$

Two-dimensional global, gotten via exponentiation of an infinitesimal transformation, conformal transformations correspond to *entire* (no singularities, invertible everywhere), *holomorphic* functions $z \rightarrow f(z)$ with holomorphic inverses $f^{-1}(z)$. The only allowable form for a conformal transformation that corresponds to an entire, holomorphic function is linear in the complex coordinates

$$f(z) = \alpha z + \beta, \text{ where } \alpha, \beta \in \mathbb{C}. \quad (22)$$

We may expect a larger group of symmetries with entirety and holomorphism enforced, since the space seems less constrained, but this actually constrains the space more and the group becomes smaller. So, if we were to not compactify, and add infinity as a point, as we demonstrated, the conformal space becomes linear and boring: only rotations and scaling are allowed.

To include this complex representation of the spacetime coordinates, we *extend* our manifold to the complex numbers \mathbb{C} and compactify complex space to a Riemann sphere $\mathbb{C} \cup \{\infty\}$ we get the proper space for the conformal transformations to act in

$$\mathbb{R}^{2,0} \rightarrow \mathbb{C} \rightarrow \mathbb{C} \cup \{\infty\} \rightarrow \text{Conf}(\mathbb{C} \cup \{\infty\}) \quad (23)$$

Where the conformal group is

$$\text{Conf}(\mathbb{C} \cup \{\infty\}) = \left\{ f(z) = \frac{\alpha z + \beta}{\gamma z + \delta}; \alpha, \beta, \gamma, \delta \in \mathbb{C}, \alpha\delta - \beta\gamma \neq 0 \right\}. \quad (24)$$

This is also called the group of Moebius transformations, and is a slightly larger group of conformal transformations (symmetries), since we can map to and from infinity as a point.

Summary

A conformal field theory is a local quantum field theory that is invariant under the conformal group, a set of transformations, a change in coordinates, that leave the metric invariant up to a scale factor. In different spacetime dimensions, the conformal group takes on significantly different forms.

The global conformal group in dimensions greater than two is comprised of translations, rotations, scaling, and special conformal transformations, as well as dimensions equal to two, as long as the space is compactified. If singularities are included, functions with poles are allowed, the symmetry gets larger.

Lecture 2: Local Conformal Transformations

In the last lecture we introduced global conformal transformations/symmetries of some manifold M that form a (symmetry) group G which can be promoted to a symmetry group of some quantum system, where the kinematics of the system are described by a Hilbert space \mathcal{H} . The quantum system is said to be globally conformally invariant if there is some unitary representation, operators U that act on the Hilbert space,

$$U : G \rightarrow U(\mathcal{H}). \quad (25)$$

Recall that in the generalized Minkowski space $\mathbb{R}^{p,q}$, the structure of the group of global conformal transformations G consists of compositions of translations, dilations, rotations(boosts), and special conformal transformations (SCTs).

Here we now study the case where $d = 2$, which will expand our notion of what a symmetry is and will allow us to define local, infinitesimal conformal transformations.

For example, a global conformal transformation, a $1-1$ differentiable map from $\mathbb{R}^2 \rightarrow \mathbb{R}^2$, may consist of a dilation and a rotation and look like

For contrast, consider an infinitesimal conformal transformation $\text{id} + \epsilon X$, where $X = X(x)$ is a vector field, the derivative of a diffeomorphism, that acts on the two-dimensional Minkowski space as

This transformation preserves all of the right angles in the untransformed Minkowski space, and the action is close to the identity, such that $|x - x'| \sim \mathcal{O}(\epsilon)$. The transformation $\text{id} + \epsilon X$ is conformal to first order in ϵ , as is required by the definition of infinitesimal.

Although the vector field $X(x)$ is a generator of the infinitesimal conformal transformation, it does not necessarily define a global transformation via exponentiation, as it just may not be well defined globally.

To begin to make sense of this, consider in quantum mechanics, where we talk about quantum systems symmetric under a group G with Hilbert space

$$(\mathcal{H}, U : G \rightarrow U(\mathcal{H})). \quad (26)$$

So, in quantum mechanics, we are reduced to finding these unitary representations of G . If G is finite, it does not make sense to speak infinitesimally (e.g., one one-hundredth of a reflection).

We assume G is a manifold, and then we may as well go as far to assume that G is a Lie group with an associated Lie algebra \mathfrak{g} , which consists of vector fields that exponentiate to the Lie group. Then the quantum system is symmetric under the Lie algebra if you get a representation

$$(\mathcal{H}, \pi : \mathfrak{g} \rightarrow L(\mathcal{H})) \quad (27)$$

Where $L(\mathcal{H})$ is the set of (bounded and unbounded) linear operators, and π generates a unitary operator on the Hilbert space, such that $\pi(X) = e^{isX}$, $s \in \mathbb{R}$.

Note that for an infinite-dimensional group, (1) the operator e^{isX} may not be continuous, and (2) the Lie algebra may not exponentiate to a Lie group, which we will encounter in conformal field theory. In other words, in contrast to when we used infinitesimal quantities to build global representations, we find that infinitesimal conformal transformations don't necessarily exponentiate to

a group.

Therefore, in the infinitesimal case, we abandon looking for (full, continuous) unitary representations of the Lie group, and instead focus in on finding Hermitian representations that generate the Lie algebra.

Local algebra of infinitesimal conformal transformations

Recall that for global conformal transformations, we have $z \rightarrow f(z)$, where f is holomorphic with inverse f^{-1} . For infinitesimal f , this transformation, including the complex conjugate, becomes

$$z \rightarrow z + \epsilon(z) \text{ and } \bar{z} \rightarrow \bar{z} + \bar{\epsilon}(\bar{z}) \quad (28)$$

Where ϵ is a holomorphic function. A convenient choice of basis, which is infinite dimensional, is

$$\epsilon_n(z) = -\epsilon z^{n+1}, \text{ where } n \in \mathbb{Z}. \quad (29)$$

Given a diffeomorphism $[z \rightarrow z + \epsilon_n(z)] = e^{\epsilon \ell_n}$, the corresponding vector field tangent to every point in the manifold is defined by the operators

$$\ell_n \equiv -z^{n+1} \partial_z \text{ and } \bar{\ell}_n \equiv -\bar{z}^{n+1} \partial_{\bar{z}}. \quad (30)$$

These differential operators form a basis, since they obey the commutation relations (**Exercise**)

$$[\ell_m, \ell_n] = (m - n) \ell_{m+n} \quad (31)$$

$$[\bar{\ell}_m, \bar{\ell}_n] = (m - n) \bar{\ell}_{m+n} \quad (32)$$

$$[\bar{\ell}_m, \ell_n] = 0. \quad (33)$$

They also as form a closed, infinite-dimensional Lie algebra $\forall m, n \in \mathbb{Z}$, called the Witt algebra $\text{Witt} = \mathcal{A} \oplus \bar{\mathcal{A}}$, where \mathcal{A} is generated by $\{\ell\}$, and $\bar{\mathcal{A}}$ is generated by $\{\bar{\ell}\}$. Everything commutes in the basis, so the direct sum of the Witt algebra is justified.

The Witt algebra is generated infinitesimally, and could also be used to infinitesimally generate a Lie group. This turns out to be true, but the Lie group is not the conformal group.

Which operators ℓ_n correspond to global transformations?

Consider a vector field

$$v(z) = - \sum_{n=-\infty}^{\infty} v_n \ell_n = \sum_{n=-\infty}^{\infty} v_n z^{n+1} \partial_z. \quad (34)$$

For this vector field to correspond to a global transformation, $v(z)$ must exponentiate to a holomorphic map f , which is nonsingular in the limit as $z \rightarrow 0$. This places constraints on the coefficients of the vector field

$$v_n = 0, n < -1. \quad (35)$$

The inverse of the vector field must also exponentiate to a holomorphic map f^{-1} , which is nonsingular in the limit as $z \rightarrow \infty$ (e.g., exists on the Riemann sphere). This places the constraint on the coefficients of the vector field:

$$v_n = 0, n > 1. \quad (36)$$

Note that if we demand holomorphicity on the full complex plane without compactifying, the only allowed global transformations will be linear transformation (**Exercise**). By compactifying $\pm\infty$ as a point onto the Riemann sphere, we have more freedom in allowed global transformations.

With these constraints in place, we are left with three (six with complex conjugates) generators of infinitesimal global conformal transformations

$$\{\ell_{-1}, \ell_0, \ell_1\} \cup \{\bar{\ell}_{-1}, \bar{\ell}_0, \bar{\ell}_1\}. \quad (37)$$

The generators close to form a subalgebra under the commutator bracket $[\cdot, \cdot]$ defined above (**Exercise**), and generate the group of *linear fractional (Möbius) transformations*, also known as the projective special linear group $\text{PSL}(2, \mathbb{C})$

$$z \rightarrow \frac{az + b}{cz + d}, \quad ad - bc = 1. \quad (38)$$

The set of global conformal transformations allowed in this basis are (**Exercise**), for $s \in \mathbb{R}$,

$$\begin{aligned} \text{Translation:} \quad e^{s\ell_{-1}} &\equiv \begin{pmatrix} 1 & -s \\ 0 & 1 \end{pmatrix} && \equiv z \rightarrow z - s \end{aligned} \quad (39)$$

$$\begin{aligned} \text{Dilation:} \quad e^{s(\ell_0 + \bar{\ell}_0)} &\equiv \begin{pmatrix} \lambda & 0 \\ 0 & \lambda^{-1} \end{pmatrix} && \equiv z \rightarrow e^{-s} z \end{aligned} \quad (40)$$

$$\begin{aligned} \text{Rotation:} \quad e^{is(\bar{\ell}_0 - \ell_0)} &\equiv \begin{pmatrix} \exp(i\frac{\theta}{2}) & 0 \\ 0 & \exp(-i\frac{\theta}{2}) \end{pmatrix} && \equiv z \rightarrow e^{is} z \end{aligned} \quad (41)$$

$$\begin{aligned} \text{Special Conformal:} \quad e^{s\ell_1} &\equiv \begin{pmatrix} 1 & 0 \\ c & 1 \end{pmatrix} && \equiv z \rightarrow \frac{z}{1 + cz}. \end{aligned} \quad (42)$$

Note that for $\mathbb{R}^{d,0}$, $d > 2$, the local transformations are also global! Also note that in one-dimensional spacetime, $(1,0)$ or $(0,1)$, conformal transformations are all monotonic increasing functions $\mathbb{R} \rightarrow \mathbb{R}$.

$d = 2$ Minkowski space, $\mathbb{R}^{1,1}$

The conformal group of $\mathbb{R}^{1,1}$ is *special*.

Theorem:

A smooth map $\varphi = (u, v) : M \rightarrow \mathbb{R}^{1,1}$ from a connected subset of $M \subset \mathbb{R}^{1,1}$ is conformal (pulls back metric to a scalar multiple of the diagonal metric), iff $u_x^2 > v_x^2$ and $u_x = v_y, u_y = v_x$ or $u_x = -v_y, u_y = -v_x$.

Theorem:

Consider an infinitely differentiable function on the real line $f \in C^\infty(\mathbb{R})$, and let $f_\pm \in C^\infty(\mathbb{R}^2, \mathbb{R})$, the infinitely differentiable functions from the real line to the real plane, be defined by $f_\pm(x, y) = f(x \pm y)$. Then the map

$$\Phi : C^\infty(\mathbb{R}) \times C^\infty(\mathbb{R}) \rightarrow C^\infty(\mathbb{R}^2, \mathbb{R}^2) \quad (43)$$

$$(f, g) \rightarrow \frac{1}{2}(f_+ + g_-, f_+ - g_-) \quad (44)$$

Has the following properties

- $\text{image}(\Phi) = \{(u, v) : u_x = v_y, u_y = v_x\}$
- $\Phi(f, g)$ is conformal iff $f' > 0$ and $g' > 0$ or $f' < 0$ and $g' < 0$
- Φ is bijective iff f and g are bijective
- $\Phi(f \circ h, g \circ k) = \Phi(f, g) \circ \Phi(h, k), \forall f, g, h, k \in C^\infty(\mathbb{R}) \equiv \Phi$ is a homomorphism.

The group of orientation-preserving transformations of $M = \mathbb{R}^{1,1}$ is isomorphic to

$$(\text{Diff}_+(\mathbb{R}) \times \text{Diff}_+(\mathbb{R})) \cup (\text{Diff}_-(\mathbb{R}) \times \text{Diff}_-(\mathbb{R})) \quad (45)$$

Which consists of the infinitely-differentiable orientation-preserving maps of \mathbb{R} , diffeomorphisms of \mathbb{R} .

It is convenient to compactify $\mathbb{R}^{1,1} \rightarrow S^{1,1} \subset \mathbb{R}^{2,0} \times \mathbb{R}^{0,2}$. Then the group of orientation-preserving transformations of $M = S^{1,1}$ is isomorphic to

$$\text{Conf}(\mathbb{R}^{1,1}) \equiv (\text{Diff}_+(S^1) \times \text{Diff}_+(S^1)) \cup (\text{Diff}_-(S^1) \times \text{Diff}_-(S^1)). \quad (46)$$

This is the definition of the conformal group of Minkowski space. Typically, we throw away the second part of the union, the “ $-$ ” reversing part, since it is the same as preserving with $z \rightarrow -z$, and focus on the infinite-dimensional subgroup $\text{Diff}_+(S^1)$, which we call the *chiral half* of the conformal group. This is admissable, since the symmetries of a quantum system can be understood by the symmetries of $\text{Diff}_+(S^1)$, and the rest is easily gotten by tensor products to include the other light-cone axes.

In the next lecture, we will focus on which quantum systems are invariant under this infinite-dimensional group $\text{Diff}_+(S^1)$ by going to the Lie algebra, which turns out to be isomorphic to the Witt algebra, in the Euclidean case. The unitary representations, gotten via infinitesimal generators, of $\text{Diff}_+(S^1)$ will not be bounded below and are unstable. Therefore, *projective* unitary representations will be required, and are classified by the *central charge*.

Lecture 3: Classical Conformal Field Theory

We continue our discussion of systems that exhibit conformal symmetries. These symmetries are contained in the conformal group called $\text{Conf}(\mathbb{R}^{p,q})$, which is the connected component containing the identity of all conformal diffeomorphisms of the pseudo-Riemannian manifold $\mathbb{R}^{p,q}$.

We discussed the infinitesimal conformal transformation, which led to a Lie algebra, the Witt algebra, in $(1+1)$ and $(2,0)$ dimensions. For $d = p + q = 2$, there is a bigger symmetry group (less constrained), yielding more conserved quantities, more degrees of freedom of the system. If $d \neq 2$, the symmetry group is too constrained to be that interesting.

A *conformal theory* is a theory with a representation of the group $G = \text{Conf}(\mathbb{R}^{p,q})$. This group contains transformations corresponding to temporal translations, spatial translations, boosts, dilations, and special conformal transformations (inversion about the origin, translation, and a second inversion about the origin). So, a conformal theory has a Hamiltonian H built in, since it is the generator of time translations.

Note that in a nonrelativistic theory, we demand that the Hamiltonian H commutes with everything, which introduces symmetries of the system, but the inclusion of boosts requires a relativistically invariant theory. This constrains the theory further to allow only certain symmetries and exhibit the desired properties.

Note that the Lorentz boost mixes energy and momentum through conjugation of spatial translations to temporal translations. This conjugation requires that all types of possible transformations in a nonrelativistic theory must be represented all at once, and they are not independent of each other.

Another property we need for our theory is *locality*.

So, we have a collection of observables $\phi_a(x)$, where $x \in \mathbb{R}^{p,q}$ and $a \in I$, an index set (labels by particle types, vector quantities, etc.), which can be classical (functions on phase space), quantum (self-adjoint operators), or even probabilistic (element of ordered unit vector space).

A representation of a group of symmetries is a map π that can be

$$\text{finite } \pi : G \rightarrow M_n(\mathbb{C}) \quad , \text{ the } n \times n \text{ matrices over the complex numbers} \quad (47)$$

$$\text{infinite } \pi : G \rightarrow \mathcal{B}(\mathcal{H}) \quad , \text{ the bounded operators on a Hilbert space, for example.} \quad (48)$$

The concern is that a given representation does not necessarily yield a set of observables $\phi_a(x)$. In the event that it does, it is likely that a representation which furnishes a collection of (local) observables is *reducible*, and can be decomposed into a direct sum of *irreducible* representations, or *irreps*. This makes for an infinite number of ways to build reducible representations.

So, although we can write down an irreducible representation of G and attempt to enforce locality, we prefer to take the stance, and shall from this point on, that the locality of the theory is the most important property, and find irreducible representations from there.

Classical field representations of conformal symmetries

The concept of the field easily puts forth the idea of locality, but what constraints does conformal symmetry place on a classical field?

Recall for symmetries in a classical field theory start with the action

$$S = \int d^d x \mathcal{L}(\phi, \partial_\mu \phi), \text{ where } \phi = \{\phi_a(x)\}. \quad (49)$$

By writing down the action, we have assumed (1) that the equations of motion are represented by an action and (2) that the Lagrangian density depends only on the field and its first derivatives. We have effectively thrown out all non-local theories.

So, a symmetry transformation takes a spacetime location and maps it to its image under that transformation: $x \rightarrow x'$. If the transformation is *active*, the then fields transform as well

$$\phi(x) \rightarrow \phi'(x') \equiv \mathcal{F}(\phi(x)) \quad (50)$$

Where we note that $\mathcal{F}(\phi(x))$ depends on the previous field configuration.

For example, in an active rotation of a vector field $\mathbb{R}^{2,0}$, a nontrivial representation rotates the spacetime coordinate as well as the vector at each spacetime coordinate, the field (A trivial representation will not rotate the vector.)

After the rotation, the new field configuration at x is

$$\phi'_a(x) = \sum_b \pi(\mathcal{O})_{ab} \phi_b(\mathcal{O}^{-1}x). \quad (51)$$

The trivial representation of the field component b would simply be the identity $\pi(\mathcal{O})_{ab} = \delta_{ab}$, and the fundamental, nontrivial representation is written

$$\pi(\mathcal{O})_{ab} = [\mathcal{O}]_{ab}. \quad (52)$$

How does the action S transform under a symmetry transformation?

$$S' = \int d^d x \left| \det \left(\frac{\partial x'^\mu}{\partial x^\nu} \right) \right| \mathcal{L} \left(\mathcal{F}(\phi(x)), \frac{\partial x^\nu}{\partial x'^\mu} \partial_\nu \mathcal{F}(\phi(x)) \right) \quad (53)$$

We also know that our theory is a conformal field theory, conformally invariant, conformally symmetric if the equations of motion are invariant. This is equivalent to the Lagrangian density transforming up to a total derivative

$$\mathcal{L}' = \mathcal{L} + \text{total derivative}. \quad (54)$$

Now, let's study the infinitesimal generators of the conformal group $\text{Conf}(\mathbb{R}^{p,q})$.

- Translation

$$P_\mu = -i\partial_\mu$$

- Dilation

$$D = -ix^\mu \partial_\mu$$

- Rotation (Boost)

$$L_{\mu\nu} = i(x_\mu \partial_\nu - x_\nu \partial_\mu)$$

- Special Conformal

$$K_\mu = -i(2x_\mu x'^\nu \partial_\nu - x^2 \partial_\mu)$$

Work out the commutation relations to form a Lie algebra (**Exercise**).

$$[D, P_\mu] = iP_\mu \quad (55)$$

$$[D, K_\mu] = -iK_\mu \quad (56)$$

$$[K_\mu, P_\nu] = 2i(\eta_{\mu\nu}D - L_{\mu\nu}) \quad (57)$$

$$[K_\rho, L_{\mu\nu}] = i(\eta_{\rho\mu}K_\nu - \eta_{\rho\nu}K_\mu) \quad (58)$$

$$[P_\rho, L_{\mu\nu}] = i(\eta_{\rho\mu}P_\nu - \eta_{\rho\nu}P_\mu) \quad (59)$$

$$[L_{\mu\nu}, L_{\rho\sigma}] = i(\eta_{\nu\rho}L_{\mu\sigma} + \eta_{\mu\sigma}L_{\nu\rho} - \eta_{\mu\rho}L_{\nu\sigma} - \eta_{\nu\sigma}L_{\mu\rho}) \quad (60)$$

And the rest commute.

Our task now is to find out which kinds of fields transform under the conformal group and give representations of the conformal group. We already know that a field transforming under $\text{Conf}(\mathbb{R}^{p,q})$, a general conformal transformation, transforms under the subgroup Poincaré, which is generated by translation P_μ and rotation $L_{\mu\nu}$, as

$$\phi_a(x) \xrightarrow{\text{Poincaré}} \sum_b \pi(\Lambda)_{ab} \phi_b(\Lambda^{-1}x). \quad (61)$$

Let's focus on the subgroup of $\text{Conf}(\mathbb{R}^{p,q})$ which leave the origin fixed: rotations, dilations, and SCTs. The infinitesimal generators of this subgroup form a subalgebra by exponentiation

$$\Lambda = e^{i\omega^\alpha G_\alpha}, \text{ where } \omega^\alpha \text{ is infinitesimal.} \quad (62)$$

The group element G_α can be K_μ , D , or $L_{\mu\nu}$. At the origin, the Poincaré transformation of the field looks like

$$\phi_a(x=0) \rightarrow \sum_b \pi(e^{i\omega^\alpha G_\alpha})_{ab} \phi_b(\Lambda^{-1}x=0) \quad (63)$$

Where the representation is, by Taylor expansion,

$$\pi(e^{i\omega^\alpha G_\alpha}) = \pi(\mathbb{I}) + i\omega^\alpha \pi(G_\alpha). \quad (64)$$

Rename the representations of the generators (group elements)

$$\pi(D) = \tilde{\Delta}(\text{scaling dimension}) \quad (65)$$

$$\pi(K_\mu) = \kappa_\mu \quad (66)$$

$$\pi(L_{\mu\nu}) = S_{\mu\nu}(\text{spin}). \quad (67)$$

The commutation of these representations are then

$$[\tilde{\Delta}, S_{\mu\nu}] = 0 \quad (68)$$

$$[\tilde{\Delta}, \kappa_\mu] = -i\kappa_\mu \quad (69)$$

$$[\kappa_\mu, \kappa_\nu] = 0. \quad (70)$$

Now, suppose that the generators $S_{\mu\nu}$ are irreducible representations, irreps, of the Lorentz group, the group that describes spin/helicity. By Schur's lemma (**Exercise**), we find that the scaling dimension is trivial, and, in turn, by the commutation relations, that all generators κ_μ are also trivial

$$\tilde{\Delta} \propto \mathbb{I} \implies -i\kappa_\mu = 0. \quad (71)$$

Now use this fact to show how dilations act on the fields. The coordinates transform as

$$x \rightarrow \lambda x \quad (72)$$

$$x \rightarrow \lambda^\epsilon \lambda^\epsilon \dots \lambda^\epsilon x \quad (73)$$

At the origin, the field transforms as

$$\phi_a(x=0) \rightarrow (\mathbb{I} + i\epsilon\tilde{\Delta}) \dots (\mathbb{I} + i\epsilon\tilde{\Delta})\phi_a(0) \quad (74)$$

$$= \lambda^{i\tilde{\Delta}_a} \phi_a(0) \quad (75)$$

$$= \lambda^{-\Delta_a} \phi_a(0) \quad (76)$$

Where we used the Taylor expansion of the infinitesimal ϵ , and the last line uses $\tilde{\Delta} = i\Delta\mathbb{I}$, since Schur's lemma tells us that the scaling dimension is trivial.

So, every conformal field has a behavior under dilations, defined by the scaling dimension Δ_a , with Jacobian

$$\left| \frac{\partial x'}{\partial x} \right| = \Lambda^{-\frac{d}{2}}, \text{ where } \Lambda = \lambda^{-2}. \quad (77)$$

And the metric transforms under dilations as

$$g'_{\mu\nu} = \lambda^{-2} g_{\mu\nu}. \quad (78)$$

Putting all this together, the field now transforms as

$$\phi_a(x) \rightarrow \phi'_a(x') = \left| \frac{\partial x'}{\partial x} \right|^{-\frac{\Delta_a}{d}} \phi_a(x). \quad (79)$$

Filling in the Jacobian, the new field in terms of the original field and the original spacetime location is

$$\phi'_a(x) = \sum_b \pi(\Lambda)_{ab} \phi_b(\Lambda^{-1}x) \quad (80)$$

$$= \sum_b [\lambda^{-\Delta}]_{ab} \phi_b(\Lambda^{-1}x) \quad (81)$$

$$= \lambda^{-\Delta} \phi_a(\Lambda^{-1}x) \quad (82)$$

$$= \lambda^{-\Delta} \phi_a(\lambda^{-1}x). \quad (83)$$

By the Baker-Campbell-Hausdorff (BCH) formula, we know how the new field looks at all spacetime locations, not just the origin (**Exercise**)

$$e^{ix^\rho P_\rho} D e^{-ix^\rho P_\rho} = D + x^\nu P_\nu \quad (84)$$

$$\implies D\phi_a(x) = (-ix^\nu \partial_\nu + \tilde{\Delta})\phi_a(x). \quad (85)$$

In the next lecture, we give this the quantum treatment, where we will look for unitary representations (self-adjoint operators), that are labelled by quantum numbers, such as spin, scaling dimension, and central charge. The central charge will require projective unitary representations.

Lecture 4:
